ABSTRACT

In the last decade Peer to Peer technology has been thoroughly explored, because it overcomes many limitations compared to the traditional client server paradigm. Despite its advantages over a traditional approach, the ubiquitous availability of high speed, high bandwidth and low latency networks has supported the traditional client-server paradigm. Recently, however, the surge of streaming services has spawned renewed interest in Peer to Peer technologies. In addition, services like geolocation databases and browser technologies like Web-RTC make a hybrid approach attractive.

In this paper we present algorithms for the construction and the maintenance of a hybrid P2P overlay multicast tree based on topological distances. The essential idea of these algorithms is to build a multicast tree by choosing neighbours close to each other. The topological distances can be easily obtained by the browser using the geolocation API. Thus the implementation of algorithms can be done web-based in a distributed manner.

We present proofs of our algorithms as well as practical results and evaluations.

KEYWORDS

Distributed algorithms, peer-to-peer (P2P), hybrid, overlay multicast tree, live streaming

1. INTRODUCTION

Peer-to-Peer (P2P) streaming has become more and more popular nowadays again after interest in general P2P has generally decreased after the initial enthusiasm in the late 90 – partially due to the ubiquitous and quick availability of high speed, high bandwidth and low latency networks which has supported the traditional client-server paradigm in the last decade. The central strength of P2P streaming systems is the capability of sharing resources so that larger (and more costly) servers can be replaced by smaller (and cheaper) computers. The P2P networks are build usually as a logical overlay network. The contribution of this paper is the construction and management of a P2P multicast tree streaming overlay where the nodes are physically close to each other in
the underlying network. In this paper we present two algorithms. The first is the joining algorithm that each node runs when it enters the system. The essential idea of the algorithm is to construct a multicast tree structure by finding a suitable neighbour in the overlay multicast tree and considering resources of peers. The second algorithm handles a host leaving that occurs gracefully or accidentally. For both algorithms we provide full mathematical proofs of minimality features. In addition, we present some experimental results and evaluations. And finally we conclude our paper with remarks on possible future work.

2. RELATED WORKS

In recent years a number of P2P-based applications for stream delivery have been developed – e.g. Zattoo (http://zattoo.com), PPTP (http://www.pptv.com) and Octoshape (https://octoshape.com).

To improve the scalability and to optimise the usage of resources in the P2P network, several approaches have been proposed. In [1] various problems that arise due to the fact of P2P systems being highly dynamic and heterogenous are examined. It focuses especially on resilience mechanisms. In [2] and [6] an overview of application and network layer mechanisms are presented and the Mesh and Multiple-Tree P2P overlays are compared.

Several applications have been developed for various categories of mesh based P2P streaming. The authors of [8] and [7] present a hybrid approach for overlay construction and data delivery in an application-layer multicast. The HyPO approach in [7] optimizes the overlay by organizing peers with similar bandwidth ranges in a geographical area into a mesh overlay. The ToMo approach in [7] combines the strong points of a tree-based structure and a mesh-based data delivery to a two-layer hybrid overlay. The mTreebone of [9] is a collaborative tree-mesh design that leverages both mesh and tree structures. The key idea is to identify a set of stable nodes to construct a tree-based backbone with most of the data being pushed over this backbone. AnySee [5] is a mesh based P2P system in which resources are assigned based on their locality and delay.

In the present work we propose algorithms to construct a tree based multicast overlay based on topological distances. Similar approaches are described in [12], [3] and [14]. Already in [20] an architecture has been proposed for designing a global internet host distance estimation service. However, only relatively recently geographical information has become practically available from freely available geolocation databases [16], and therefore ideas which have been of theoretical value only have now become practical, see also [19]. The approach used in [12] and [3] organizes the peers into a hierarchy of clusters such that the neighboring peers are grouped into the same cluster. The overlay network is build from the cluster leaders to the other members recursively. In [14] a locality-aware P2P overlay construction method, called Nearcast, is proposed which builds an efficient overlay multicast tree by letting each peer node choose physically closer nodes as its logical children. Whereas there is rather comprehensive coverage of theoretical P2P algorithms and mathematical theorems on some of them like e.g. the T-Man protocol, see [4], up to our best knowledge, no minimality results have been proven for the overlay networks like the one described above but rather simulation results have been computed. In our work we propose algorithms which minimise the routing costs, usage of peer resources and end-to-end delay based on the topological location of peers. We provide a proof for the minimality of routing costs and provide evidence for keeping end-to-end delay low.
3. PROPOSED APPROACH

The concept of P2P multicasting [11], [12] is often applied to reduce the costs needed to deploy and to maintain services related to streaming of various content to many users, e.g. VoD, IPTV, radio, news channels, etc. In this paper, we propose an approach to the construction of a P2P overlay multicast tree with the goal to solve the following important problems:

- **Optimal routing between peers:** Transmission at an overlay P2P-network might be inefficient, especially when the P2P-network is randomly constructed. This stems from the fact that the distance between peers physically or topologically is not considered by constructing the P2P-network.

- **Optimal usage of peer resources:** Peer resources include available bandwidth, processing power and storage space.

- **End-to-End delay:** The end-to-end delay is the latency, accumulated peer by peer, for the delivery of a data packet along the overlay path from the source host to an end host. To reduce this delay the height of the multicast tree should be kept small.

- **Handling of peer connections:** In practice the P2P-network need to deal with peers joining the network and peers that leave voluntarily or due to failure.

![Figure 1. Topological search tree and p2p multicast tree structure.](image)

To overcome these problems, we propose algorithms for the construction and the management of an overlay P2P-network. Our algorithms use the topological distances between peers to guarantee the optimal routing costs. We define two data structures, a topological search tree and a P2P multicast tree (fig. 1). The search tree is used to find the nearest peer to be attached to the multicast overlay. This a special case of the Nearest Neighbour Search (NNS) or closest point search problem. Donald Knuth named this problem the post office problem [10]. The problem relates to an application of the assignment to the next post office. In our case the problem is reduced to the search in the tree and adapted for the search of an optimal usage of peer resources. The P2P multicast tree is used for the actual data transfer.
4. P2P OVERLAY MULTICAST TREE CONSTRUCTION AND MAINTENANCE

4.1. Definitions and Preliminaries

To identify the topological position of hosts in a network, a unique H-dimensional coordinate $C$ is assigned to each host. The idea to use the network coordinates is based on considerations from [13], [14] and [15]. In contrast to the algorithms presented therein, we use in our approach two data structures: the search tree $T_s$ for searching the nearest neighbour according to the topological position in the network and the multicast tree $T$ to connect hosts to a P2P overlay multicast network.

The multicast overlay tree is defined as $T = (V, E)$, where $V$ is a set of vertices, which represent the end hosts, and $E$ is a set of directed edges, which represent data delivery streams between the end hosts.

The search tree $T_s$ is considered as an $H$-layered topological tree. According to the topology of the search tree $T_s$ for each vertex $v \in V$ the network coordinate $C(v)$ is defined as follows:

$$C(v) = \{C_{H-1}(v), \ldots, C_0(v)\}$$  \hspace{1cm} (1)

Similarly to the Nearestcast method proposed in [14] we use static network coordinates and assign to the vertices (end hosts in the physical network) special geographical meanings. The coordinates $C_{H-1}(v), \ldots, C_0(v)$ represent Regional Internet Registry, Country, City and $n$-th bits of an IP-address respectively e.g:

\{RIPE, DE, HH, 80.x.x.x, 80.6.x.x.., 80.6.60.x\}
\{ARIN, US, NIC, 10.x.x.x, 10.7.x.x., 10.7.50.x\}

The geographical information can be easily obtained from the freely available geolocation databases [16] by using the programming interfaces described in [17] and [18]. Formally the search tree $T_s$ can be defined using tuple notation as $T_s = (V_s, E_s)$, where

$$V_s = \bigcup C(v)$$  \hspace{1cm} (2)

and

$$E_s = \bigcup_{0 < i < (H-1)} \{(C_i(v), C_{i+1}(v))\}.$$  \hspace{1cm} (3)

Finally we introduce a hierarchical common network distance $D$ and last common coordinate $LCC$, used by our algorithms. The hierarchical common network distance $D$ between two vertices $v_x$ and $v_y$ with the static network coordinates:

$$C(v_x) = \{C_0(v_x), \ldots, C_i(v_x), \ldots, C_{H-1}(v_x)\}$$
$$C(v_y) = \{C_0(v_y), \ldots, C_i(v_y), \ldots, C_{H-1}(v_y)\}$$

is the number of coordinates with different values and is denoted as $D(v_x, v_y)$. Formally the hierarchical common network distance is defined as:
4.2. Joining algorithm

To construct a multicast overlay tree the joining algorithm connects the hosts to an overlay network by analysing the geolocation information provided by the end hosts. The algorithm can be implemented in a centralized or a distributed manner. The pseudocode of the joining algorithm is shown in fig. 2.

**Algorithm JOIN (new, T_s)**

1. $T_s = T_s \cup C(new)$
2. find the nearest neighbour $n$ of new in $T_s$;
3. attach new to $n$;

---

Figure 2. The pseudocode of the JOIN algorithm

Figure 3 illustrates an example of the joining nodes to an existing overlay network. Initially the overlay multicast tree contains only a source host $S$ and the search tree $T_s$ includes the coordinates $C(S)$ (fig. 3a). To attach the new node $v_1$ the joining algorithm extends the search tree $T_s$ by the adding the coordinates $C(v_1)$ and determines the nearest host by traversing the search tree $T_s$. The nearest neighbour can be easily found by a simple tree traversing in $O(\log n)$ time. The new host $v_1$ is attached to the host $S$ (fig. 3b). The fig. 3c illustrates the attaching of the host $v_2$ to the multicast overlay tree.

To show that the routing in the constructed multicast tree $T$ is optimally organised, we assign to each edge $e = \{v_0, v_1\}$ a topological distance value $D(e) := D(v_0, v_1)$, that represents the routing costs between the vertices $v_0$ and $v_1$. It is easy to check that $D$ satisfies all axioms of a metric which is important for the minimality results presented in the sequel (only the triangle inequality is non-trivial). The sum of all distances $S(T) = \sum_{e\in E} D(e)$ is the total routing costs in the tree. The lower the value $S(T)$ is, the less
Routing overhead is necessary to deliver the content to each vertex in the multicast tree. The topological distance can be thought of a proxy for the “real” distance measured as End-to-End-Delay or other QoS parameters. In the literature (see e.g. [21]) it has been argued, that the topological distance is a reasonable proxy in practice. As next we show that our algorithm constructs a multicast tree $T$ with minimal routing costs. In other words it is not possible to construct another multicast tree $T_1$ with $S(T_1) < S(T)$.

**Theorem 1.** The algorithm $JOIN$ (fig. 2) constructs a tree $T$ with the minimal $S(T)$ value.

*Proof.* The correctness of the algorithm is proved by induction on the number of vertices in $T$.

*Base case:* $T = \emptyset$ or $|T| = 1$ are trivially minimal.

*Induction step:* Assume that $S(T)$ is minimal for $n$ connected vertices. Let $v_{n+1}$ be the next vertex added to the multicast tree $T$ and $v \in T$ is the nearest neighbour of $v_{n+1}$ (fig. 4a). Let us show that $S(T) + D(v,v_{n+1})$ is minimal.

Consider any multicast trees $T'$, where $v_{n+1}$ not connected to $v$. We will see that there is no tree with $S(T') < S(T)$.
First assume the vertex $v_{n+1}$ is connected to any vertex $v' \in T \setminus v$ as a leaf (fig. 4b). It is easy to see that $S(T') \geq S(T) + D(v, v_{n+1})$, because $D(v', v_{n+1}) \geq D(v, v_{n+1}) \forall v'$ as $v$ is a nearest neighbour.

Thus, the $S(T')$ value could only be possibly reduced by connecting the vertex $v_{n+1}$ such that an edge $e = \{v_x, v_y\}$ with $D(v_x, v_y) > D(v, v_{n+1})$ is removed from $T$ (fig. 4c). Removing an edge from the tree breaks it into two separate subtrees $T_1'$ and $T_2'$. The vertex $v_y$ is the root of the subtree $T_2'$, because it is the successor of the vertex $v_x$. In order to connect two subtrees the vertex $v_y$ must be connected to the vertex $v_{n+1}$ as a successor and the vertex $v_{n+1}$ is connected to a vertex $v_i$ in $T_1'$. It is possible that $v_i = v_x$ or $v_i = v_n$, if $v_n \in T_1'$.

With $T' = (T \setminus \{v_x, v_y\}) \cup \{v_{n+1}, v_y\} \cup \{v_i, v_{n+1}\}$, let us assume the following inequality being strict:

$$S(T') < S(T) + D(v, v_{n+1}) \tag{6}$$

The $S(T')$ value of $T'$ can be calculated from the definition as:

$$S(T') = S(T) - D(v_x, v_y) + D(v_{n+1}, v_y) + D(v_i, v_{n+1})$$

As $v$ has minimal distance, by replacing the $S(T')$ in the inequality (6) we get:

$$-D(v_x, v_y) + D(v_{n+1}, v_y) + D(v_i, v_{n+1}) < D(v, v_{n+1})$$

Thus, $D(v_x, v_y) > D(v_{n+1}, v_y)$ and $D(v_x, v_y) > D(v_i, v_{n+1})$.

However, from the definition of topological distances in the search tree $T_s$ (fig. 5) the following must be true:

$$\begin{align*}
(D(v_x, v_y) = D(v_{n+1}, v_y)) \land (D(v_x, v_y) > D(v_i, v_{n+1})) \\
(D(v_x, v_y) > D(v_{n+1}, v_y)) \land (D(v_x, v_y) = D(v_i, v_{n+1}))
\end{align*} \tag{7}$$

But (7) contradicts inequality (6). Thus $S(T) + D(v, v_{n+1})$ is minimal. □

The algorithm $JOIN$ (fig. 2) may construct different trees depending on selection of the nearest neighbour and the order the nodes joining, however the next theorem shows that $S(T)$ is not affected.
Theorem 2. All trees constructed by the algorithm JOIN (fig. 2) have the same $S(T)$ value.

Proof. Assume that algorithm JOIN (fig. 2) constructs two different trees $T_0$ and $T_1$ for the same set of vertices (end hosts) with $S(T_0) \neq S(T_1)$.

According the theorem 1 the value of $S(T_0)$ and the value of $S(T_1)$ are minimal. Since $S(T_0) \neq S(T_1)$, follows that either $S(T_0)$ or $S(T_1)$ is not minimal. So the assumption must be incorrect. □

The algorithm JOIN (fig. 2) solves the routing costs problem, mentioned in the section 3. However the algorithm does not consider the usage of peer resources. As next we present an extension of the algorithm JOIN to solve the peer capacity problem.

4.3 Management of peer-resources

To manage the usage of peer resources the attribute resource capacity is assigned to each host in the network model. The resource capacity of an end host, denoted by $R(v)$, is a maximum number of outgoing links $e \in E$, which can be served by the vertex $v$. The value $R(v)$ is calculated based on available bandwidth and other resources of the peer.

The pseudocode of the joining algorithm with the peer-resource management $JOIN_R$ is shown in fig. 6 (we call $v$ in $LCC(new,n)$ iff $LCC(new,v) = LCC(new,n)$). To join a new node the algorithm $JOIN_R$ finds the nearest neighbour $n$, similar to the algorithm JOIN (fig. 2). Instead of attaching the node directly to the nearest neighbour $n$ found, the algorithms checks all existing hosts with the same topological distance as the vertex $n$, whether one of the vertices has enough resources to forward the data link to the new

Algorithm $JOIN_R (new, T_s)$

\begin{verbatim}
1 $T_s = T_s \cup C(new)$
2 /* $n$ is a potential neighbour of $new$ */
3 for (all reachable hosts $v$ in $LCC(new,n)$) {
4    if($R(v) != 0$) {
5       attach $new$ to $v$;
6       $R(v) = R(v) - 1$;
7       return;
8    }
9 }
10 for (all reachable hosts $v$ in $LCC(new,n)$) {
11    for (all hosts $v_x$ connected to $v$) {
12       if($D(v, new) \leq D(v, v_x)$) {
13          insert $new$ between $v$ and $v_x$;
14          $R(new) = R(new) - 1$;
15          return;
16       }
17    }
18 }
\end{verbatim}

Figure 6. The pseudocode of the $JOIN_R$ algorithm
node. For that the last common coordinate \( LCC \) according the definition 5 (section 4.1) is calculated. If one appropriate host \( v \) is found the new node is attached and the resource capacity attribute of the host \( v \) is updated. Otherwise the algorithms checks again all reachable hosts and verifies if the new node can be inserted between a host \( v \) and any hosts connected to \( v \) with \( D(new, v) \leq D(v_x, v) \).

![Diagram of JOINR execution](image)

**Figure 7. An example of the algorithm JOINR execution**

Figure 7 illustrates an example of the algorithm \( JOIN_R \) execution. We define for this example the following condition \( \forall v \in V : R(v) = 3 \). In other words each host is able to maintain three outgoing links.

Initially the overlay multicast tree contains only a source host \( S \) and the search tree \( T_s \) includes the coordinates \( C(S) \) (fig. 7a).

To attach the new node \( v_1 \) the algorithm \( JOIN_R \) adds the coordinates \( C(v_1) \) to the search tree \( T_s \) and determines the nearest host of \( v_1 \) (fig. 7b). The host \( v_1 \) is attached to the host \( S \) and the \( R(S) \) value is updated accordingly \( R(S) = 3 - 1 = 2 \).

Figure 7c illustrates the attaching of the host \( v_2 \). After updating the search tree \( T_s \) the algorithm \( JOIN_R \) checks all potential nearest neighbours, reachable from the \( LLC = RIPE \). In order to find the \( LLC \)-value, it is enough to traverse backwards the search tree \( T_s \) from the vertex \( v_2 \) until the first branch. The potential nearest neighbours of \( v_2 \) are the hosts \( S \) and \( v_1 \), because \( D(S, v_2) = D(v_1, v_2) = 2 \). The host \( v_2 \) is attached to the host \( S \) and the \( R(S) \) value is updated accordingly \( R(S) = 2 - 1 = 1 \).

The attaching of the host \( v_3 \) (fig. 7d) is similar to the previous step. The \( R(S) \) value is updated to \( R(S) = 1 - 1 = 0 \). The host \( S \) can not maintain any further outgoing links.

The last figure 7e illustrates the attaching of the host \( v_4 \). The nearest neighbour of \( v_4 \) is \( S \). But \( R(S) = 0 \) and there are no other free potential neighbours with the same topological distance. The algorithm \( JOIN_R \) checks in this case all potential nearest neighbours \( v \) whether any hosts \( v_x \) with \( D(v, v_4) \leq D(v, v_x) \) is connected to \( v \). In our case:
\[ D(S, v_4) = 0 \leq D(S, v_1) = 1 \]
\[ D(S, v_4) = 0 \leq D(S, v_2) = 2 \]
\[ D(S, v_4) = 0 \leq D(S, v_3) = 1 \]

So the algorithm \( JOIN_R \) inserts the host \( v_4 \) between \( S \) and \( v_1 \) and updates the \( R(v_4) \) value accordingly \( R(v_4) = 3 - 1 = 2 \).

Similar to the algorithm \( JOIN \) (fig. 6) we show that the routing in the constructed multicast tree \( T \) is optimally organised, i.e. that \( S(T) \) is minimal and that the algorithm solves the resource capacity problem \( R(T) \) as defined below. In order to do so we assign to each vertex \( v \in V \) a resource value \( R(v) \) that represents the maximum number of outgoing data links which can be served by the vertex. We call \( R(T) \) solved if \( \forall v \in V : R(v) \leq R_{\max}(v) \).

Admittedly the algorithm constructs a multicast tree with minimal \( S(T) \) value and solves the resource capacity problem \( R(T) \) with respect to a following precondition:

\[ \forall v \in V : R_{\max}(v) > 0 \] (8)

**Theorem 3.** The algorithm \( JOIN_R \) (fig. 6) constructs a tree \( T \) with the minimal \( S(T) \) value and solves the resource capacity problem \( R(T) \).

**Proof.** The algorithm \( JOIN_R \) consists of two parts, each one performing a loop on the potential nearest neighbours \( v \) of the host \( new \).

The first part is reduced to the algorithm \( JOIN \) (fig. 2) and proved by induction (theorem 1). If the first loop detects a nearest neighbour, then it must have at least one free outgoing link to attach a new vertex. So \( S(T) \) is minimal and \( R(T) \) is solved.

The second loop is only executed if all potential nearest neighbours have no capacity. According the precondition 8 each vertex must be able to serve at least one outgoing link. It follows that one of the potential nearest neighbours must be connected to a vertex \( x \) with the topological distance \( D(v, x) \geq D(v, new) \) (fig. 8a). The vertex \( x \) is reconnected to the vertex \( new \) (fig. 8b). \( D(v, x) = D(new, x) \), because \( v \) is one of the nearest neighbours of \( new \). This step can be reduced to the algorithm \( JOIN \) (fig. 2) and proved by induction (theorem 1). So \( S(T) \) is minimal. According the precondition 8 the vertex \( new \) must be able to serve an outgoing link to \( x \) and \( R(T) \) is solved. \( \square \)

In the next section we present an extension of the algorithm to reduce the end to end delay.

![Diagram](image-url)

Figure 8. Proof of the second loop.
4.4 End-to-End Delay

An important performance metric that is of concern for live media streaming overlays is the End-to-End Delay. The End-to-End Delay (EED) depends on the underlying network delay and the local delays at overlay peers due to queuing and processing. Formally we define the EED as a delay of the path $p = \{v_0, \ldots, v_n\}$ from the source host $v_o$ to the end host $v_n$:

$$EED = \sum_{i=0}^{\left|p\right|} D(v_i, v_{i+1}) + \left|p\right|$$

(9)

We use the sum of the topological distances to represent the logical delay in the network and number of overlay hosts to represent the local delays at overlay peers. The algorithm $JOIN_R$ constructs an overlay multicast tree $T$ by choosing topologically close peers as neighbours. The $S(T)$ value is minimal (theorem 3), so the delay in the network is minimal. To reduce total End-to-End Delay it is necessary to minimize the number of peers on the delivery path $p$. So the total End-to-End Delay depends on the multicast tree height. In order to keep the End-to-End Delay small we adapted the algorithm $JOIN_R$ for construction a low stretched multicast tree as follows:

1. The loops on the potential nearest neighbours $v$ of the host new are executed in the sorted order. The potential nearest neighbours are sorted by the End-to-End Delay to the source host according the equation (9).

2. The insert procedure (Fig. 9: lines 15-17) is modified. The host new is inserted between the host $v$ and the host $v_x$ with the lowest End-to-End Delay according to equation (9). And the outgoing links of $v_x$ are reattached to new as long as $R(new) > 0$.

The pseudocode of the joining algorithm $JOIN_{RE}$ is shown in figure 9 (we call $v$ in $LCC(new, n)$ iff $LCC(new, v) = LCC(new, n)$). Since the basic structure of the algorithm $JOIN_{RE}$ is equal to the structure of the algorithm $JOIN_R$, the algorithm satisfies the conditions of the theorem 1 and 3. For example in fig. 7c the potential nearest neighbours of the host $v_2$ are $S$ and $v_1$. But the host $S$ has the lower EED-value, so the host $v_2$ is attached to $S$. The host $v_1$ is attached to $S$ (fig. 7d), because $S$ has the lowest EED-value and has enough resources.

In fig. 7e the host $v_4$ can be inserted between three potential hosts $v_3$, $v_1$ and $v_2$. According to equation 9 the $EED(S, v_3) = 2$, $EED(S, v_1) = 2$ and $EED(S, v_2) = 3$. So the host $v_4$ is inserted between $S$ and $v_1$.

The modified algorithm $JOIN_R$ keeps the End-to-End Delay small because the multicast tree height is logarithmic to the number of hosts. The total End-to-End Delay is $O(\log N)$. 
Algorithm $JOIN_{RE} (new, T_h)$

1. $T_s = T_s \cup C(new)$
2. /* $n$ is a potential neighbour of $new$ */
3. for (all reachable hosts $v$ in $LCC(new, n)$ in sorted order by EED) {
   4.     if ($R(v) != 0$) {
      5.         attach $new$ to $v$;
      6.         $R(v) = R(v) - 1$;
      7.         return;
      8.     }
   9. }
10. for (all reachable hosts $v$ in $LCC(new, n)$ in sorted order by EED) {
   11.     for (all hosts $v_x$ connected to $v$) {
      12.         if ($D(v, new) \leq D(v, v_x)$) {
      13.             insert $new$ between $v$ and $v_x$;
      14.             $R(new) = R(new) - 1$;
      15.             while ($R(new) > 0$ or $v_x$ has outgoing links) {
      16.                 reattach an outgoing link of $v_x$ to $new$;
      17.             }
      18.             return;
      19.         }
   20. }
21. }

Figure 9. The pseudocode of the JOINRE algorithm

4.5 Reconstruction algorithm

In order to support handling of peer connections we propose an algorithm to handle a host departure that may occur on purpose or by accident accidentally.

The pseudocode of the reconstruction algorithm is shown in figure 10. The algorithm deletes a host if it is a leaf. Otherwise it tries to reattach the outgoing links to the parent as long as it has enough resources. Finally the algorithm executes the algorithm $JOIN$ for remaining hosts.

5. EXPERIMENTAL EVALUATIONS

In this section, we present simulation results for evaluation of the proposed approach. We have implemented a simulation to create overlay multicast trees according to our approach and as a balanced binary tree. The simulation parameters are: number of hosts and the resource capacity of each host $R$. The simulation calculates the routing costs in the tree $S(T)$ according the definition in section 4.2, the height of the tree $H(T)$ and the End-to-End Delay (EED) according to the equation 9 (section 4.4).

The tables 1 and 2 present the results of the comparison a multicast tree constructed by the $JOIN$-Algorithm with a randomly constructed balanced binary tree with the $R(v) = 3$
Algorithm RECONSTRUCT_TREE ($v_{del}$)

1. if ($v_{del}$ is a leaf) {
  2. delete $v_{del}$;
  3. } else {
  4. $v_p$ = parent of $v_{del}$;
  5. for (each child $v$ of $v_{del}$ in sorted order) {
  6.   if ($R(v_p) > 0$) {
  7.     reattach $v$ to $v_p$;
  8.     $R(v_p) = R(v_p) - 1$;
  9.   }
 10.  } else {
 11.  JOIN($v$, $T_a$);
 12.  }
14. }

---

</tbody>
</table>

the same value in the tree with $R(v) = 2$ and $R(v) = 3$. The reason is that the algorithm always chooses the nearest neighbour and the routing costs are kept minimal. The End-to-End Delay depends on the height of the tree and the $R(v)$ value respectively.

The chart 11 shows the End-to-End delay dependency graphically.

If the EED-value of the tree generated by the algorithm JOIN increases only slightly, then the EED-value of the binary balanced tree generated increases dramatically. In the real $P2P$ overlay multicast tree each peer is able to serve different number of outgoing resources. The trend of EED delay dependency will remain definitely similar.
6. CONCLUSION

In this paper we presented a novel multicast tree construction and maintenance approach based on the topological network coordinates of the end hosts. The algorithms presented in this paper were developed to achieve the following desirable properties:

– Minimal routing overhead in the underlying network
– Optimal resource management of the hosts
– Short end-to-end delay

We evaluated our approach theoretically and by using simulations. Compared to the randomly generated trees our approach improves significantly the performance metrics of a multicast overlay tree. Our future work will concentrate on implementing this approach in a real environment, collecting and analysing the performance data.
